Translational T-box riboswitches bind tRNA by modulating conformational flexibility

T-box riboswitches are noncoding RNA elements involved in genetic regulation of most Gram-positive bacteria. They regulate amino acid metabolism by assessing the aminoacylation status of tRNA, subsequently affecting the transcription or translation of downstream amino acid metabolism-related genes. Here we present single-molecule FRET studies of the *Mycobacterium tuberculosis IleS* T-box riboswitch, a paradigmatic translational T-box. Results support a two-step binding model, where the tRNA anticodon is recognized first, followed by interactions with the NCCA sequence. Furthermore, after anticodon recognition, tRNA can transiently dock into the discriminator domain even in the absence of the tRNA NCCA-discriminator interactions. Establishment of the NCCA-discriminator interactions significantly stabilizes the fully bound state. Collectively, the data suggest high conformational flexibility in translational T-box riboswitches; and supports a conformational selection model for NCCA recognition. These findings provide a kinetic framework to understand how specific RNA elements underpin the binding affinity and specificity required for gene regulation.

Protein synthesis, or translation, is an essential cellular activity in all known cellular life. The biologically active substrates required for translation are aminoacyl-tRNAs (charged tRNAs), which are synthesized by aminoacyl-tRNA synthetases. To ensure an adequate supply of charged tRNAs, several regulatory mechanisms have evolved[1]. In Gram-positive bacteria, one such mechanism is represented by T-box riboswitches. Riboswitches are *cis*-acting RNA elements that undergo structural changes in response to a regulatory signal[2,3]. While numerous riboswitches regulate gene expression in response to various small molecule metabolites[3], T-box riboswitches recognize and respond to the aminoacylation state of tRNAs[4]. A higher proportion of uncharged tRNAs compared to charged tRNAs indicates a shortage of a specific amino acid or aminoacyl-tRNA synthetase[5]. By detecting intracellular concentrations of uncharged tRNAs, T-box riboswitches, located at the 5′ leader region of the mRNAs that they regulate, can alter the

transcription or translation of aminoacyl tRNA synthetase genes or other amino acid metabolism-related genes[6–8]. Aside from the ribosome, T-box riboswitches are the only other known RNA capable of both tRNA identity decoding and aminoacylation sensing[8], and thus provide a unique paradigm for gene regulation by two interacting, structured non-coding RNAs[4,6,9,10].

As is the case with other riboswitches; T-box riboswitches are modular and composed of two parts, a ligand binding domain and an expression platform. tRNA decoding and aminoacylation status discrimination reside in two separate structural domains (Fig. 1a). T-box riboswitches have an obligatory Stem I domain that decodes tRNA identity[11–13]; this process is often facilitated by Stem II and Stem IIA/B domains[6,14]. In general, Stem I, Stem II, and Stem II A/B comprise the decoding module (Fig. 1a), except for glycine T-box riboswitches, where Stem II and Stem IIA/B are absent. To achieve specificity, the

Fig. 1 | Structure and mechanism of the *Mtb-ileS* T-box riboswitch. a Secondary structure diagram showing the *Mtb-ileS* T-box riboswitch (pink/red) and tRNA[Ile] (blue). The T-box has two distinct structural domains, the decoding module (red) is involved in recognizing specific tRNAs through anticodon-specifier interactions (cyan, green), whereas the discriminator domain (pink) contains the T-box sequence (brown) involved in recognizing the 3′ NCCA region of the tRNA (purple) and assessing the aminoacylation status. The two domains are joined by a linker region (yellow). The secondary structure diagram is based on the structure of the complex[14]. **b** Proposed mechanism for translation-regulating T-box riboswitches. The T-box decodes the tRNA identity of the tRNA and aminoacylation status at the 3′ end. Depending on the aminoacylation status of the tRNA, it exposes or sequesters the Ribosome Binding Site or Shine Dalgarno sequence (SD, green). If the tRNA is uncharged, the 3′ NCCA of the tRNA forms base pairs with the T-box sequence leading to a conformation where the SD region is accessible, and translation is allowed (top). If the tRNA is charged, the interactions with the T-box sequence are precluded, leading to a conformation where the SD and the Anti Shine Dalgarno (ASD, cyan) regions interact, the SD is inaccessible, and translation is not allowed (bottom). **c** Structure of the *Mtb-ileS* T-box riboswitch/tRNA[Ile] complex[14]. The molecules are colored as in (**a**). The top two pictures show two orientations of the complex. The bottom picture shows a model of a truncated T-box missing the Discriminator domain (Δ-Discriminator mutant). Approximate distances between the 3′ and 5′ ends of the T-box (69 Å), the 3′ end of T-box and the 5′ end of the tRNA (40 Å), and the 3′ end of the Δ-Discriminator Mutant and the 5′ end of the tRNA (29 Å) are shown.

tRNA anticodon pairs with a single codon sequence in the T-box RNA, known as the specifier sequence, which is situated in the specifier loop of Stem I. The discriminator domain examines the aminoacylation status of the tRNA and switches the expression output appropriately[14,15](Fig. 1b). The discriminator domain includes Stem III, an antiterminator or antisequestrator region, and the T-box sequence (AGGGUGGNACCGCG), which comprises the 14 most highly conserved nucleotides of the complete T-box RNA (Fig. 1a) and is involved in recognition of the NCCA sequence at the 3′ end of the tRNA.

The majority of T-box riboswitches regulate gene expression at the transcription level[16–18]. In the absence of tRNA, or in the presence of charged tRNA, transcription-regulating T-box riboswitches typically adopt an intrinsic terminator structure that promotes premature termination of transcription. Alternatively, binding of an uncharged cognate tRNA promotes the formation of an antiterminator structure that enables transcription readthrough. The *Bacillus subtilis glyQS* T-box riboswitch, as a representative transcription-regulating T-box riboswitch, has been the subject of extensive structural and kinetic studies[11,13,15,19]. Single-molecule characterization of the *glyQS* T-box riboswitch established a two-step binding model in which the anticodon of tRNA[Gly] is recognized first, leading to a partially bound state, followed by binding of the tRNA[Gly] 3′ NCCA end, leading to a fully bound state[19,20]. In addition, an intramolecular conformational change between the decoding and the discriminator domains occurs during the second binding step. Notably, in this model, binding of the tRNA[Gly] ligand by the *glyQS* T-box riboswitch follows the directionality of transcription, with kinetic parameters supporting a cotranscriptional binding and switching mechanism. Specifically, the short lifetime (~4 sec) of the partially bound state allows rapid sampling of the anticodon sequence and ensures that the tRNA remains bound until synthesis of the discriminator domain occurs. On the other hand, the fast transition into the fully bound state when the uncharged NCCA end is present, effectively locks the T-box riboswitch into the antiterminator conformation. Finally, the fully bound state is very stable to allow for transcription readthrough beyond the T-box regulatory sequence.

Translation-regulating T-box riboswitches achieve gene regulation via tRNA-induced conformational changes from a sequestrator conformation, which occludes the Ribosome Binding Site (RBS) sequence, to an antisequestrator conformation, which makes the RBS accessible to the ribosome (Fig. 1b)[21]. While the core structural domains for anticodon recognition and aminoacylation discrimination are highly similar between the translation and transcription-regulating T-box riboswitches, translation-regulating T-box riboswitches contain distinct structural elements[14]. Compared to their transcription-regulating counterparts, translation-regulating T-box riboswitches have a shorter Stem I. Stem I in the *glyQS* T-box riboswitch provides an additional contact with the elbow region of the tRNA that greatly facilitates the first binding step of the tRNA to the riboswitch[13,15]. The absence of this critical interaction in translation-regulating T-box riboswitches is partially compensated for by additional interactions provided by Stems II and IIA/B at the anticodon binding pocket[6,14]. However, it is unclear whether these structural differences lead to different binding kinetics in translation-regulating T-box riboswitches. In addition, transcription-regulating riboswitches are limited to cotranscriptional regulation since a decision must be made before transcription of the coding region. In contrast, translation-regulating T-box riboswitches allow for the synthesis of the full transcript, opening the possibility that translation-regulating T-box riboswitches could perform several rounds of regulation throughout the lifetime of the mRNA. Thus, the two types of riboswitches may have evolved to have different structural dynamics that accommodate their functional differences[22]. Kinetic studies of the tRNA binding mechanisms and associated conformational dynamics of translational T-box riboswitches are necessary to elucidate these differences. While recent kinetic characterizations of translation-regulating T-box riboswitches lacking the discriminator domain have provided mechanistic insights into the conformational landscape of the decoding module and its response to tRNA binding[23,24], it remains unknown how conformational dynamics at the decoding module communicate with the rest of the T-box to coordinate their actions, information which is essential to understand the function of these riboswitches.

Here, the interactions between tRNA and a translational T-box riboswitch are investigated using a combination of single-molecule Förster resonance energy transfer (smFRET), ensemble binding assays, and mutagenesis. The use of a translational T-box riboswitch construct including both decoding and discriminator modules enabled kinetic characterization of the full binding process. The results reveal a two-step tRNA binding process with overall similarities to the binding process observed for transcription-regulating T-box riboswitches, but with distinct kinetic features. Particularly, the data presented here supports a conformational selection model for binding of the tRNA NCCA end. In addition, our results highlight critical structural elements at the decoding and discriminator modules that kinetically facilitate tRNA binding efficiency and specificity. This work provides a comprehensive picture of the tRNA binding kinetics of a translational T-box riboswitch, illuminating important biophysical differences between translation- and transcription-regulating T-box riboswitches.

Results

Preparation of fluorophore-labeled *Mtb ileS* T-box riboswitch

The *Mycobacterium tuberculosis ileS* T-box riboswitch (*Mtb ileS* T-box) was chosen as a model system to study translational T-box riboswitches due to the availability of a crystallographic structure of the complex, which encompasses a significant portion of the T-box riboswitch sequence[14]. The structural information served as a valuable reference to guide the experimental design. Initially, a construct was designed including a 15-nucleotide extension at the 5′ end of the in vitro transcribed T-box RNA, which allowed annealing to a modified DNA probe for immobilization. Purification of this transcript by urea-polyacrylamide gel electrophoresis (urea-PAGE), followed by direct Cy3 labeling at the 3′ end, and in vitro refolding in the presence of a biotinylated oligonucleotide resulted in no measurable tRNA[Ile] binding. This was likely due to the presence of the 5′ extension, which was impeding in vitro refolding of the T-box transcript. To address this issue, a T-box construct was designed employing an alternative labeling method as follows. The 15-nucleotide extension used for immobilization was appended to the 3′ end of the transcript, downstream of the antisequestrator domain. This construct encompasses Stem I, Stem II, Stem II-A/B, the linker sequence, Stem III, and the antisequestrator (nucleotides 1- 166, Fig. 1a). However, it lacks the region spanning the RBS, thereby precluding the transition to the sequestrator conformation. During in vitro transcription, a DNA oligonucleotide complementary to the 3′ extension was added to the reaction. The DNA oligonucleotide carried the donor dye (Cy3) at its 3′ end and a biotin on the 5′ end. The labeled and biotinylated oligonucleotide allows for surface immobilization of the *Mtb-ileS* T-box via biotin-streptavidin interaction, and also places the donor dye in proximity to the 3′ terminus of the T-box construct for smFRET measurements (Fig. 1c) once hybridized (Fig. 2a). Positioning of the extension at the 3′ end of the riboswitch ensured that the decoding module would have an opportunity for vectorial folding during transcription, and that only full-length transcripts would anneal the oligonucleotide and be observed in smFRET imaging.

The *Mtb ileS* T-box was purified directly from the transcription reaction by size exclusion chromatography (SEC) under conventional conditions[25]. This process yielded readily distinguishable fractions of both unfolded and folded *Mtb-ileS* T-box states (Supplementary Fig. 1a). The folded population of *Mtb-ileS* T-box molecules is consistent with their predicted apparent molecular weight, considering that the substantial negative charge of the molecule due to the phosphate backbone results in a larger hydration shell. The apparent molecular weight of an RNA is 3−5 times larger than a globular protein of comparable molecular weight and hence elutes from a SEC column significantly earlier[25]. SEC purification also facilitated direct comparison of the overall folding of the wild-type (WT) construct with engineered mutants, ensuring that any binding differences were not due to misfolding (Supplementary Fig. 1a). After transcription and SEC purification, the fraction corresponding to the fully transcribed and correctly folded *Mtb ileS* T-box riboswitch, already annealed to the biotinylated and Cy3 labeled DNA oligonucleotide, was used for smFRET imaging. The purified material was further analyzed by denaturing PAGE to confirm the integrity and purity of the *Mtb ileS* T-box for each species (Supplementary Fig. 1b). Additionally, the purified material was analyzed by SEC after one week of storage at the conditions used in this study to ensure the conformational homogeneity and stability of the samples (Supplementary Fig. 1c). The elution profiles of the samples after storage were nearly identical to the initial purification, indicating that the samples maintained their structural integrity during storage. In summary, the design with a 3′ extension, together with direct purification of the T-box construct from the transcription reaction via SEC avoided denaturation and refolding of the T-box riboswitch, which could disrupt its function. For intermolecular smFRET experiments with the cognate tRNA ligand, an acceptor fluorophore (Cy5) was conjugated at the 5′ end of the *M. tuberculosis* tRNA[Ile] molecule (Methods). The purification of the tRNA was carried out by urea-PAGE, followed by refolding using standard procedures (Methods).

Biolayer Interferometry (BLI) binding assays were used to assess the effect of fluorescent labeling on tRNA binding to the Cy3-labelled *Mtb ileS* T-box (Supplementary Fig. 2a). For the BLI assays, the *Mtb ileS* T-box purified as described above was immobilized on the biosensor. tRNA association was measured in a solution containing uncharged tRNA[Ile]. After measuring the tRNA[Ile] association, the biosensor was immersed in a tRNA[Ile]-free solution to enable tRNA[Ile] dissociation detection. To fit the BLI data, three different binding models were considered: one-step binding, parallel one-step binding, and sequential two-step binding (Supplementary Fig. 2b). The binding and dissociation curves were fit most accurately by the two-step sequential binding model (Supplementary Fig. 2c). The apparent equilibrium dissociation constant (K_D) was calculated using the two-step sequential binding model as described in the Supplementary Information section. The K_D of *Mtb ileS* T-box binding to tRNA[Ile] obtained in these assays agrees well with previously reported affinities for this T-box class[21]. K_D with Cy5-labeled tRNA[Ile] (0.89 μM) was increased by only 2 to 3-fold compared to unlabeled tRNA[Ile] (0.42 μM), demonstrating that the introduction of a label at the 5′ end of tRNA[Ile] resulted in only a moderate impact on the binding affinity (Supplementary Fig. 2d, Supplementary Table 1). This effect is milder than that previously reported for the *B. subtilis glyQS* T-box riboswitch[19].

Uncharged tRNA[Ile] stably binds to the *Mtb ileS* T-box

Time-lapsed single-molecule fluorescence images of *Mtb ileS* T-box were captured in the presence of 100 nM tRNA[Ile]-Cy5 at equilibrium conditions (Fig. 2b). The distribution of FRET efficiency values resulting from tRNA[Ile]-Cy5 binding displays two main populations, with mean values of 0.4 and 0.7 (Fig. 2c, Supplementary Table 2). Furthermore, the presence of a zero FRET state in the histograms can be attributed to both unbinding and acceptor fluorophore photobleaching events. The observed distribution is the result of three types of behaviors (Fig. 2b and Supplementary Table 3). 77.3 % of traces (Type I) sample only the 0.7 FRET state in addition to the zero FRET state. Among Type I traces, the majority of traces (91.8%, Type I-1) display a single, stable signal at 0.7 that undergoes single step photobleaching. A small population (8.2 %, Type I-2) shows transitions from zero to 0.7 FRET efficiency. 17.8% of traces (Type II) sample only the 0.4 state in addition to the zero FRET state, either once or several times before photobleaching. Finally, a very small fraction of traces (Type III traces, 4.9%) sample both the 0.7 and 0.4 states.

In most cases, unless specified otherwise, Global Hidden Markov Modeling (HMM) was used to simultaneously model all trajectories of
Fig. 2 | smFRET experiments show binding of tRNA^{Ile} to the wild-type *Mtb-ileS* T-box riboswitch. a Schematic diagram illustrating the smFRET experiment. The T-box was anchored to the surface via hybridization to a DNA oligonucleotide (purple) biotinylated on the 5' end and Cy3-labeled at the 3' end. The tRNA^{Ile} was labeled on the 5' end with Cy5. Cartoon based on a similar cartoon from[19]. **b** Representative Cy3 (green) and Cy5 (red) fluorescence intensity (top) and smFRET trajectories (bottom) of the *Mtb-ileS* T-box riboswitch/tRNA^{Ile}. The smFRET efficiency was calculated as ($I_{Cy5}/(I_{Cy3}-I_{Cy5})$). Three types of trajectories were observed: Type I trajectories only show FRET efficiency around 0.7, Type II trajectories only show FRET values around 0.4, and Type III trajectories sample the 0.4 and 0.7 states. **c** FRET efficiency histogram of the data. Dotted black lines show the individual populations obtained from the consensus HMM modeling, while the model's population-weighted set of efficiency distributions is plotted with a solid black line. N reports the number of traces included in the histogram. **d** Transition density plot constructed using the idealized Viterbi paths modelled to the entire dataset using tMAVEN[26]. The contour level colors report the normalized counts. N reports the total number of transitions. **e** Dwell time survival plot for the 0.4 and 0.7 FRET states. The data were fitted using either a single (0.7 state) or double (0.4 state) exponential decay function. The number of events (N) used for the analysis and the fitting parameters are shown. Data are shown in blue and the fitting curves are shown in dotted black lines. The fit residuals are shown in the bottom plot. Detailed fitting results are reported in Supplementary Table VI. each particular experimental condition[26]. Transition frequencies (Supplementary Table 4), transition rates from an initial state to a final state (Supplementary Table 5), and state dwell times (Supplementary Table 6) were revealed by this HMM modeling approach. Throughout this work, the transition rates between two FRET states as described by transition matrices is emphasized (Supplementary Table 5). The lifetime of a state before transitioning out of that state −to any other states− from dwell time analysis is also determined (Supplementary Table 6). In addition, the lifetime of a given state was also estimated using the reciprocal of the sum of transition rates out of that state from the transition matrices (Supplementary Table 5). This calculation is largely consistent with the dwell time analyses in the instances hereby presented.

Type I traces predominantly demonstrate transitions from the 0.7 state to the zero FRET state (22.7%, calculated as the number of transitions of this type over the total number of transition events), consistent with the fact that 71.0% of traces (Type I-1) show stable 0.7 FRET before transitioning into the zero state. In contrast, transitions from the zero to the 0.7 state are the least frequent (2.4%, from Type I-2 traces) (Supplementary Fig. 3a). The less frequent Type II traces also contribute to a large number of transition events from 0.4 to zero FRET (25.2%) and from zero to 0.4 FRET (12.7%) (Supplementary

Fig. 3b), as a fraction of Type II traces sample the 0.4 state multiple times in each trajectory. 0.4 to zero FRET transitions are more frequent than the reverse transitions as the former also include the photobleaching step. Finally, Type III traces demonstrate inter-state transitions between 0.7 and 0.4 FRET states (20.2% for 0.7 to 0.4 transitions and 16.7% for 0.4 to 0.7 transitions) (Supplementary Fig. 3c, Fig. 2d, Supplementary Table 4).

According to the crystal structure[14], there should be a distance of approximately 40 Å between the labeling positions at the 3' end of the *Mtb ileS* T-box and the 5' end of the tRNA (Fig. 1c). The 0.7 FRET value obtained from the measurements is within the predicted range of FRET values, assuming a Förster distance of 40−50 Å for Cy3-Cy5 FRET pair[27]. Hence, it is plausible to designate the 0.7 FRET state as the fully bound state of tRNA[Ile] to the *Mtb ileS* T-box. The large population of Type I traces and 0.7 to zero transitions indicate that, preponderantly, the tRNA[Ile] was fully bound to the T-box prior to data collection. This state persisted until the acceptor fluorophore photobleached, thus restricting the observed lifetime of the 0.7 state to 26.9 s (Fig. 2e and Supplementary Table 6). The characteristics of the 0.7 state are strikingly similar to those of the fully bound state of *B. subtilis glyQS* T-box riboswitch in complex with uncharged tRNA[Gly19]. This similarity is expected due to the structural conservation between antisequestrator and antiterminator domains of translational and transcriptional T-boxes, respectively, in complex with their cognate tRNAs (Supplementary Fig. 3d)[14,15].

While the nature of the 0.4 FRET state is not clear from the data above, there are more frequent transitions from the zero to the 0.4 state (12.7%) than from the zero to the 0.7 state (2.4%), suggesting that binding of tRNA[Ile] is more likely to result in this unknown intermediate state (0.4 FRET) than the fully bound state (Fig. 2d, Supplementary Fig. 3a, b, Supplementary Table 4). The lifetime of the 0.4 FRET state is consistently estimated to be 7.0 s, based on a transition rate of 0.144 s^{-1} out of the 0.4 FRET state in the transition matrix (Supplementary Table 5), and 7.4 s from the dwell time analysis (Fig. 2e, Supplementary Table 6). It was noticed that the dwell time of the 0.4 FRET state is better described by a double-exponential decay, consistent with the presence of two transition pathways and potential populational heterogeneity (see sections below). It should be noted that the binding rate of tRNA[Ile] to either the unknown intermediate or fully bound states from the unbound state is likely to be underestimated by these experiments, given that the majority of the population probed was already in the fully bound state during the data acquisition time window (Supplementary Fig. 8).

Anticodon recognition leads to a partially bound state of the tRNA

The nature of the 0.4 state cannot be deduced from the available structural data. However, it resembles a state observed in studies of the *B. subtilis glyQS* T-box riboswitch[19]. In the *glyQS* T-box, a 0.4 state corresponds to a partially bound state in which only the anticodon/specifier interactions have been established. To test whether the 0.4 FRET state in *Mtb ileS* T-box represents such partially bound state, two experiments were devised. In the first experiment, smFRET measurements were conducted with the *Mtb ileS* T-box using a tRNA[Ile] variant lacking the terminal NCCA-3' sequence (tRNA[Ile-ΔNCCA]-Cy5). It was anticipated that tRNA[Ile-ΔNCCA]-Cy5 would only be able to bind to the decoding module but not to the discriminator domain (Fig. 3a). Using this tRNA substrate, two apparent populations were initially identified

Fig. 3 | smFRET experiments show consequences of the absence of the NCCA/specifier interactions. a Schematic diagram illustrating the smFRET experiment with the tRNA[Ile-ΔNCCA]-Cy5 construct. Cartoon based on a similar cartoon from[19]. **b** FRET efficiency histogram for tRNA[Ile-ΔNCCA]-Cy5 mutant. Fitted populations using consensus HMM modeling are shown as in Fig. 2c. **c** Transition density plot for tRNA[Ile-ΔNCCA]-Cy5 mutant for all data constructed using the idealized Viterbi paths modelled with tMAVEN[26], plotted the same way as described in Fig. 2d. **d, e** Dwell time survival plots for the 0.5 FRET state. The data were fitted using either a single (left) or double (right) exponential decay function. The double exponential decay function better fits the data. in the FRET efficiency distribution: a 0.5 FRET state and a zero FRET state (Fig. 3b, Supplementary Table 2). The largely diminished 0.7 FRET state further supports the assignment of the 0.7 FRET to represent the fully bound state. Hence, the presence of the 0.5 FRET efficiency state was ascribed to a partially bound state in which no interactions with the NCCA sequence had occurred and only the tRNA anticodon region was bound. Symmetrical transitions between the two FRET states were observed (Fig. 3c). The transition rate from the zero state to the 0.5 state was $0.019\,s^{-1}$, while the transition rate from the 0.5 state to the zero state was $0.053\,s^{-1}$ (Supplementary Table 5), corresponding to an average lifetime of 18.8 s before tRNA dissociation, which is consistent with a lifetime of 17.3 s determined by dwell time analysis (Fig. 3e, Supplementary Table 6). Again, it was noticed that the dwell time histogram of the 0.5 FRET state is better described by a double exponential decay, similar to the case of the 0.4 FRET state when using tRNA^{Ile} (Fig. 3d, e).

In a second experiment, a mutant of the *Mtb ileS* T-box which prevents tRNA^{Ile} interactions through the NCCA sequence was constructed by eliminating the discriminator domain (Δ-Discriminator Mutant, nucleotides 1-93). The SEC elution profile of the Δ-Discriminator Mutant resembles that of the wild-type *Mtb ileS* T-box, with the exception that the peak of interest eluted at a later volume (Supplementary Fig. 1). This shift was anticipated due to the lower molecular weight of the construct. The deletion of the discriminator domain had an impact on the ability of the T-box to bind to tRNA^{Ile}, as demonstrated by BLI measurements. The K_D increased from 0.42 μM for the wild type, to 4.03 μM for the mutant (Supplementary Table 1), corresponding to a ~10-fold reduction in the binding affinity. smFRET analysis on this mutant using tRNA^{Ile}-Cy5 (Fig. 3f) yielded two distinct populations centered at zero and 0.66 FRET respectively (Fig. 3g, h, Supplementary Table 2). Symmetrical transitions between the two FRET states were observed (Fig. 3i and Supplementary Fig. 4f). The transition rate from the zero to the 0.66 state was $0.0134\,s^{-1}$, whereas the transition rate from the 0.66 state to the zero state was $0.0568\,s^{-1}$. This corresponds to a 0.66 FRET state average lifetime of 15.5 seconds, consistent with 16.1 seconds as calculated by dwell time analysis (Supplementary Tables 5 and 6). The lifetime of the 0.66 FRET state resembles the lifetime of the 0.5 FRET state in the case of WT T-box with tRNA$^{Ile-\Delta NCCA}$. However, interestingly, the dwell time of the 0.66 FRET state can be well described with a single-exponential decay (Fig. 3j).

For the Δ-Discriminator Mutant, the estimated distance between the truncation position and the 5' end of the tRNA is around 29 Å (Fig. 1c). The observed higher FRET efficiency at 0.66 would be expected for a Förster distance of 40 to 50 Å[27]. This effect is likely caused by a collapse of the single-stranded linker region in the absence of the discriminator domain, with which it normally establishes contacts (Fig. 1c). However, as the transition rates between the zero and 0.5 states in the WT T-box with tRNA$^{Ile-\Delta NCCA}$-Cy5 and between the zero and 0.66 states in the Δ-Discriminator T-box mutant with tRNA^{Ile}-Cy5 are similar (Supplementary Table 5), both the 0.5 and the 0.66 FRET states were interpreted to correspond to the same partially bound state. The absence of the NCCA sequence may allow the decoding module to shift the 5' end of tRNA$^{Ile-\Delta NCCA}$-Cy5 closer to the discriminator domain; leading to an apparently higher FRET efficiency state compared to the 0.4 state observed in the case of WT T-box with tRNA^{Ile}-Cy5. Taken together, the results presented so far suggest a two-step binding model in which the interactions between the tRNA NCCA and anticodon with the T-box do not happen simultaneously.

tRNA anticodon binding precedes NCCA recognition in *Mtb ileS* T-box

The above experiments demonstrate that the *Mtb ileS* T-box can identify the anticodon region of tRNA^{Ile} in the absence of the NCCA sequence. Furthermore, two previous studies with translational

T-boxes missing the discriminator domain[23,24] corroborate this finding. Nevertheless, to determine if interactions between *Mtb ileS* T-box and the NCCA sequence are possible without anticodon recognition, additional experiments were pursued. First, tRNA^{Trp}-Cy5 was introduced into a flow chamber containing pre-immobilized *Mtb ileS* T-box, but no binding of tRNA^{Trp}-Cy5 was detected. Binding by BLI was also not detectable. Second, an additional T-box construct was designed in which the specifier region, responsible for identifying the cognate anticodon, was mutated to recognize tRNA^{Trp} instead (AUC mutated to UGG), hereafter referred to as the Specifier Mutant. The Specifier Mutant fraction eluted slightly earlier than the WT *Mtb ileS* T-box in SEC analysis (Supplementary Fig. 1), likely due to a potential contribution of the specifier sequence in maintaining the native conformational landscape of the decoding module[24]. No binding was observed when tRNA^{Ile}-Cy5 was added to a flow-chamber pre-immobilized with the Specifier Mutant. Consistent with the smFRET measurements, BLI assays measured the K_D of tRNA^{Ile} binding to the Specifier Mutant to be 120.4 μM, three orders of magnitude larger than the K_D of WT *Mtb ileS* T-box (0.42 μM) (Supplementary Table 1), and well above the expected physiological concentrations of tRNA[28].

Overall, the results of these experiments confirm that tRNA binding requires the specifier region to recognize the tRNA anticodon before interactions with the NCCA sequence can be established. The experiments also suggest that the translation-regulating *Mtb ileS* T-box follows the same sequential binding mechanism as the transcription-regulating *B. subtilis glyQS* T-box.
The partially bound state in *Mtb ileS* T-box exhibits conformational heterogeneity

While *Mtb ileS* T-box follows the same sequential binding mechanism as *B. subtilis glyQS* T-box, the presence of conformational heterogeneity in the partially bound state of *Mtb ileS* T-box complex with tRNA$^{Ile-\Delta NCCA}$-Cy5 was observed, as indicated by the double exponential fitting of the dwell time data of the 0.5 FRET state (Fig. 3e). This conformational heterogeneity is absent in the *B. subtilis glyQS* T-box case[19]. Specifically, two distinct types of traces were observed upon tRNA$^{Ile-\Delta NCCA}$-Cy5 binding to the WT *Mtb ileS* T-box: a population where the 0.5 FRET state is briefly sampled, either once or multiple times (72.7 %) (Fig. 4a and Supplementary Tables 2 and 3), and a second population where the 0.5 FRET state is sampled constantly until photobleaching (27.3 %) (Fig. 4e and Supplementary Tables 2 and 3).

In light of this finding, the two subpopulations were further analyzed separately. For the subpopulation that was briefly sampling the 0.5 state (Fig. 4a, b), transitions were identified via composite HMM, i.e., where individual trajectories are modeled separately[26]. This approach is more sensitive to FRET states sampled by a few data points per trajectory. Composite HMM analysis revealed homogeneous transitions between 0.5 state and zero state in this population (Fig. 4c, Supplementary Fig. 4c). The dwell time of the 0.5 FRET state in this subpopulation can be fit with a single-exponential decay function, yielding an average lifetime of 6.4 s (Fig. 4d and Supplementary Table 6). This subpopulation, named One-state population, was reminiscent of the case of tRNA$^{Gly-\Delta NCCA}$-Cy5 binding to the WT *B. subtilis glyQS* T-box, in which the dwell time of the partially bound state was described well with single exponential decay function with a similar lifetime[19].

Remarkably, molecules that apparently spent a longer time in the 0.5 FRET state actually displayed rapid transitions to a 0.7 FRET state, the latter reminiscent of the FRET efficiency observed in the fully bound state (Fig. 4e, f). In this subpopulation, named Two-state population, the 0.7 FRET state was very transiently sampled by 1-2 time points (<200 ms), which was not initially captured by the global HMM algorithm. In order to model accurately this fast transition behavior, Gaussian mixture modelling (GMM)[26] was used (see Methods). Since

the short-lived 0.7 FRET state is consistently sampled across the dataset of this subpopulation, this approach, which assumes that all the data points originate from a mixture of a finite number of Gaussian distributions with unknown parameters, is capable of detecting it. The GMM analysis revealed that transition events occurred predominantly between the 0.7 and 0.5 FRET states (92.2% of total transitions) (Fig. 4g and Supplementary Table 4). These FRET states displayed short lifetimes, 0.52 s and 0.16 s for the 0.5 and 0.7 FRET states, respectively (Fig. 4h and Supplementary Table 6).

In summary, these results suggest that, upon anticodon recognition, the *Mtb ileS* T-box exhibits fast conformational dynamics, unlike the *B. subtilis glyQS* T-box. In the absence of the 3′ terminal NCCA sequence in tRNA$^{\text{Ile}}$, some *Mtb ileS* T-box molecules undergo futile attempts to achieve the 0.7 FRET state, conformationally resembling

the fully bound state. In other words, the 0.7 FRET state can be transiently sampled without establishment of the NCCA-discriminator interaction. The average lifetime of the 0.5 FRET state is 4.8 s considering both the One-state and Two-state populations (Supplementary Figure 8), corresponding to a 0.21 s^{-1} transition rate out of 0.5 FRET to any other state. This rate is consistent with the total transition rate out of 0.4 FRET (0.14 s^{-1}) in the presence of WT tRNA$^{\text{Ile}}$, further confirming that the 0.5 FRET state in the case of tRNA$^{\text{Ile-}\Delta\text{NCCA}}$ and the 0.4 FRET state in the case of tRNA$^{\text{Ile}}$ both represent the partially bound state. Finally, the 0.7 FRET state in the Two-state population is unstable, with a lifetime of 0.16 s. Establishment of the NCCA-discriminator interaction in the presence of uncharged tRNA$^{\text{Ile}}$ stabilizes the 0.7 FRET by at least 160-fold, leading to a stable fully bound state (Supplementary Fig. 8).
Fig. 5 | The *Mtb-ileS* T-box riboswitch samples open and closed conformations. **a** Schematic diagram illustrating the smFRET experiment using an intramolecularly labeled *Mtb-ileS* T-box construct. Two FRET states were observed, assigned to an open (zero FRET, left) and a closed (0.3 FRET, right) state. Cartoon based on a similar cartoon from[19]. **b** FRET efficiency histograms of intramolecularly labeled *Mtb-ileS* T-box in the absence of tRNA (left), and in the presence of different concentrations of tRNA[Ile] (right, top) and tRNA[Ile-ΔNCCA] (right, bottom). The orange line corresponds to the fits of a Gaussian function to each peak. N reports the number of traces in each histogram. Only the first 40 frames from FRET trajectories are included in the histogram to avoid including data after photobleaching of the fluorophores. **c** Changes in the fraction of the closed conformation as a function of tRNA[Ile] or tRNA[Ile-ΔNCCA] concentration. The fraction of the closed state was calculated by 1) fitting Gaussian curves to each peak, which provided an estimate of the standard deviation, 2) using these fits to obtain the area under each peak by integration, and 3) calculating the fraction by dividing the area corresponding to the 0.3 FRET state by the sum of the areas corresponding to the zero and the 0.3 FRET states in (**b**). The error of each fraction was estimated by standard error propagation using the fitting uncertainties as described in the Methods section and correspond to the error bars in the figure. Source data are provided as a Source Data file.

tRNA binding alters the conformational equilibrium of *Mtb ileS* T-box

To study intramolecular conformational changes of the *Mtb ileS* T-box upon tRNA binding, a new construct was designed, termed IntraFRET. This construct has a 5' extension that enables it to bind a 5'-end Cy5-labeled DNA oligonucleotide while retaining the 3' extension used for immobilization and Cy3 labeling (Fig. 5a). This construct enables probing the distance changes between the 5' and 3' ends of the *Mtb ileS* T-box. The SEC elution profile of the IntraFRET molecule exhibited greater complexity as compared to the T-box construct with only the 3' oligonucleotide attached. This was evident by the appearance of several peaks in the chromatogram (Supplementary Fig. 1). By measuring both Cy3 and Cy5 absorbance signals from each SEC fraction, only one of the peaks was found to contain both signals. This fraction was used for smFRET analysis. This peak, corresponding to the doubly labeled T-box, eluted earlier compared to T-box with only the 3' oligonucleotide due to its higher molecular weight.

For smFRET measurements, the IntraFRET molecules were immobilized to the imaging slide and time-lapsed fluorescence images were recorded with and without tRNA. To distinguish between molecules in a potential zero FRET state from those with only a Cy3 label, five frames were recorded using direct Cy5 excitation before time-lapsed FRET imaging. In the absence of tRNA, the IntraFRET sample showed two distinct FRET states centered at zero and 0.3, respectively (Fig. 5b). We assigned these states as open (zero FRET) and closed (0.3 FRET) states. The closed state is consistent with the expected distance of around 68 Å between the 3' and 5' ends of the T-box in complex with tRNA[Ile] (Fig. 1c)[27]. Addition of tRNA[Ile] caused a dose-dependent increase in the proportion of the closed state (Fig. 5b, c). Remarkably, addition of tRNA[Ile-ΔNCCA] similarly increased the proportion of the 0.3 FRET efficiency state in a dose-dependent manner, albeit with a reduced efficiency (Fig. 5 b, c). These findings suggest that in the absence of the tRNA ligand, the *Mtb ileS* T-box samples both the open and closed conformations autonomously. The experiments with tRNA[Ile-ΔNCCA]

indicate that anticodon recognition alone increases the population of the closed state. Interactions between the NCCA end of the tRNA and the discriminator of the T-box further enhance the stability of the closed state. These observations are in stark contrast to equivalent experiments with the *glyQS* T-box, where an intramolecular conformational change is exclusively associated with the binding of both the anticodon and NCCA[19].

Stem IIA/B-linker interactions allosterically modulate tRNA binding

The linker region in *Mtb ileS T-box* (nucleotides 79–92) connects the decoding module and the discriminator domain (Fig. 1a). This linker region is predominantly stabilized by extensive interactions with Stem IIA/B, resulting in limited flexibility. Specifically, nucleotide A81 at the 5′ end of the linker forms an A-minor interaction with the G68-C77 pair in Stem IIA/B. Then, the 5′-half of the linker rests against the interface between Stems II and IIA/B and forms a pseudoknot structure by base pairing with three of the nucleotides in the loop of Stem IIA/B (Fig. 1a). Hence, it has been suggested that this pseudoknot imposes the constraints required to position the discriminator domain in proximity to the tRNA acceptor arm[14]. Disruption of the aforementioned A-minor interaction (A81G) was shown to significantly decrease the functional efficiency of the *B. subtilis tyrS* T-box[14]. To investigate how the Stem IIA/B-linker interactions modulate the tRNA binding kinetics, an *Mtb ileS* T-box mutant that included the A81G substitution as well as mutations expected to disrupt the three critical base pairs with Stem IIA/B was generated (Fig. 6a). This mutant is hereafter referred to as the "Linker Mutant". The SEC elution profile and K_D (measured by BLI) of the Linker Mutant were similar to those of the WT *Mtb ileS* T-box (Supplementary Figs. 1, 2d Supplementary Table 1).

The FRET values resulting from the binding of tRNA^Ile-Cy5 to the Linker Mutant form two populations, with mean values of 0.4 and 0.7 (Fig. 6b, Supplementary Table 2), similar to the ones observed using the WT *Mtb ileS* T-box. However, the 0.7 FRET state is much less

populated in this mutant compared to the WT T-box. With the same categorization as the one utilized for the WT construct (Supplementary Fig. 5a), Type I, II, and III traces comprise 20.3%, 46.19%, and 33.5% of the total traces, respectively (Supplementary Table 3). The reduced fraction of Type I traces, and the corresponding increase in the fractions of Type II and III traces suggest that the stability of the fully bound state is compromised in this T-box mutant.

The transitions between 0.7 and 0.4 FRET states in both directions are most frequent, accounting for 63.4% of all transitions (Fig. 6c and Supplementary Table 4). The transition rates between the 0.7 and 0.4 states are 8- to 15-fold faster in the Linker Mutant compared to those in the WT construct (Supplementary Table 5). The transitions between the 0.4 and the zero FRET states contribute to 29.4% of all transitions (Fig. 6c, Supplementary Fig. 5b and Supplementary Table 4), with the rates around 2- to 4-fold faster compared to the WT construct (Supplementary Table 5). Similar to the WT construct, transitions between zero and 0.7 FRET states were the least frequent, accounting for only 7.3% of the total (Fig. 6c, Supplementary Fig. 5b and Supplementary Table 4). Consistent with increased transition rates between the states, the average lifetime of the 0.4 state was 1.3 s, and the lifetime of the 0.7 state was 3.0 s, a ~6-fold and ~10-fold decrease compared to the corresponding state in the WT construct (Figs. 2e, 6d, e and Supplementary Table 6). These results demonstrate the importance of the A-minor interaction and pseudoknot structure in maintaining the stability of both the partially and fully bound states. Overall, these results confirm the significance of the *Mtb ileS* T-box linker region in tRNA binding and point to allosteric effects on tRNA recognition, since the Stem II A/B-linker interactions are not directly involved in tRNA binding.

The conserved RAG sequence confers specificity and stability to NCCA-Discriminator interactions
Prior structural data had provided insights into aminoacylation state sensing by the T-box discriminator domain. Specifically, a conserved

consensus sequence RAG (R = purine) plays a crucial role in this process[14]. In the *Mtb-ileS* T-box, the RAG sequence starts with G94, which interacts with nucleotide A77 at the 3′ of the tRNA and with U125 in the antisequestrator. The second nucleotide in the sequence, A95, is crucial for continuous stacking between T-box nucleotides A129 and C131. Lastly, G96 binds C131 in the antisequestrator[14]. These interactions provide the specificity required to bind an uncharged tRNA containing a terminal adenosine with intact 2′ and 3′ hydroxyl groups. This high level of specificity renders the NCCA binding pocket incompatible with any other chemical moieties, such as an attached amino acid. Indeed, single nucleotide substitutions in the RAG sequence (R94U, A95G, and G96C) significantly decrease the induction of the *B. subtilis tyrS* T-box[14]. To investigate how this RAG sequence contributes kinetically to NCCA recognition, a mutant, termed "RAG mutant," containing substitutions G94C, A95G, and G96C (Fig. 7a) was designed. The RAG mutant has a SEC elution profile that closely resembles that of the WT construct (Supplementary Fig. 1) and exhibits a moderate decrease in binding affinity to tRNA[Ile], with a K_D of 1.2 μM, compared to 0.42 μM in the WT construct (Supplementary Table 1).

Interestingly, smFRET measurements using the RAG mutant and tRNA[Ile]-Cy5 revealed a new FRET state centered at 0.9, in addition to the 0.4 and 0.7 states (Fig. 7b, Supplementary Table 2). Approximately 82.2% of the traces (Type I, II and IV) probe only one FRET state (0.7, 0.4, or 0.9, respectively) either once or a few times before photobleaching, while the remaining 17.8% of traces exhibit transitions between two or three states collectively (Supplementary Fig. 6a). Specifically, the Type II traces, representing traces only sampling of the 0.4 state, represent 17.8% of the data, similar to the WT construct. Traces sampling only the 0.7 (Type I) and only the 0.9 (Type IV) FRET states add up to 64.4%, close to the fraction of the Type I traces in the WT T-box (Supplementary Fig. 6a, b and Supplementary Table 3). This suggests that the fully bound state in the RAG mutant has two conformations corresponding to the 0.7 and 0.9 FRET states respectively. While the 0.7 FRET state corresponds to the same conformation of fully bound state observed in the WT construct, the 0.9 FRET state corresponds a new state only observed in the RAG mutant complex, hereafter referred to as the pseudo fully bound state.

The RAG mutant showed a similar frequency of transitions between 0.7 and 0.4 FRET states compared to the WT complex, albeit with two to three times faster transition rates (Supplementary Tables 4 and 5). In addition, transitions also occurred between the 0.7 and 0.9 FRET states with similar frequency as the 0.7 and 0.4 transitions, suggesting that the RAG mutant complex exhibits additional conformational dynamics between the fully bound state and the pseudo fully bound state. Finally, direct transitions between 0.4 and the 0.9 FRET states were also observed with less frequency (Fig. 7c and Supplementary Table 4). Dwell time analysis determined the average lifetime of the 0.4 state to be 3.8 s (Fig. 7d and Supplementary Table 6), reduced by ~2-fold compared to the 0.4 state of the WT construct (Fig. 2e and Supplementary Table 6), consistent with a faster transition rate from 0.4 FRET to zero FRET in the RAG mutant. The average lifetime of the 0.7 state is 9.7 s (Fig. 7e), reduced by ~2-fold compared to the lifetime of the 0.7 state in WT T-box. The lifetime of the 0.9 state is 8.8 s (Fig. 7f and Supplementary Table 6), comparable to the lifetime of the 0.7 state for this mutant. The lifetime comparison between the RAG mutant and WT construct for each FRET state indicates that: 1) the fully bound states still represent a more energetically stable conformation than the partially bound state, and 2) the mutations make the NCCA-discriminator interactions less structurally constrained by generating an energetically similar pseudo fully bound state. These findings support the notion that the conserved RAG sequence plays a crucial role in regulating the ability of the discriminator domain to sense aminoacylation, likely by restricting potential degrees of freedom of the bound ligand.

Stem II integrity is essential for proper folding of *Mtb ileS* T-box
In an attempt to investigate its dynamics and involvement in tRNA[Ile] binding, Stem II was systematically shortened to generate three additional constructs, termed Stem II mutants A, B, and C (Supplementary Fig. 7). Amongst the three, only Stem II mutant A produced a distinct peak in the SEC chromatogram (Supplementary Fig. 1). These findings suggest that Stem II mutants B and C are likely to fold into defective conformations. Stem II mutant A did not exhibit any measurable tRNA[Ile] binding, as measured by either smFRET or BLI, hence precluding further study. These results emphasize the importance of
Fig. 8 | Proposed kinetic model for the binding process of the *Mtb-ileS* T-box to tRNA. In the absence of tRNA, the T-box samples both an open and a closed conformation (left, blue background). In the presence of tRNA, the T-box binds tRNA through a two-step process where interactions with the anticodon are established first, forming a partially bound state (middle, yellow background). The partially bound state exhibits conformational heterogeneity revealed by the WT T-box/ tRNA$^{\text{Ile-}\Delta\text{NCCA}}$ complex. In the One-state subpopulation (middle, top), tRNA$^{\text{Ile-}\Delta\text{NCCA}}$ transiently binds, leading to a 0.5 FRET state, with a 6.4 s lifetime ($\tau(0.5)_{\text{partially\_1}}$) before dissociating. In the Two-state subpopulation (middle, bottom), tRNA$^{\text{Ile-}\Delta\text{NCCA}}$ remains stably bound, and rapidly fluctuates between a 0.5 FRET state (with a lifetime of $\tau(0.5)_{\text{partially\_2}}$) and a 0.7 FRET state (with a lifetime of $\tau(0.7)_{\text{partially}}$). The 0.7 FRET state in the partially bound state resembles the 0.7 FRET state in the fully bound state (right, green background), but with a much shorter lifetime due to the absence of the NCCA-discriminator interactions. In the presence of an intact, uncharged NCCA end, the NCCA end of tRNA engages with the discriminator domain, leading to a long-lived fully bound state (right, green background, $\tau(0.7)_{\text{fully}}$). Rate constants (blue) are shown for the different binding states. Rate constants for the binding and dissociation during anticodon recognition step and for the conformational fluctuations within the Two-state subpopulation of the partially bound state are determined from the experiments using WT T-box riboswitch and tRNA$^{\text{Ile-}\Delta\text{NCCA}}$ at a tRNA concentration of 100 nM. The lifetimes of all FRET states are shown in pink and are calculated from dwell time analysis (Supplementary Table 6). The lifetimes of different FRET states in the partially bound state are determined from the experiments using WT T-box riboswitch and tRNA$^{\text{Ile-}\Delta\text{NCCA}}$. The lifetime of the fully bound state is determined from the experiments using WT T-box riboswitch and tRNA$^{\text{Ile}}$. A detailed explanation of how the rates and lifetimes were assigned is given in Supplementary Fig. 8.

the integrity of the decoding module in binding tRNA$^{\text{Ile}}$. It was shown in recent single-molecule and Small Angle X-ray Scattering (SAXS) studies of the decoding module that the formation of the anticodon binding groove depends on the conformational dynamics between Stems I, II, and the Stem IIA/B pseudoknot[23,24]. The mutants presented hereby support that preserving the integrity of all stems is essential for the decoding module to maintain its natural dynamic ensemble. These results highlight the cooperative nature of the conformational landscape of *Mtb ileS* T-box.

Discussion

There has been a surge in interest in the conformational dynamics and tRNA ligand binding mechanisms of translational T-box riboswitches. The folding landscape of the decoding module (containing Stems I, II, and IIA/B) of the *Nocardia farcinica ileS* T-box riboswitch and its coupling to tRNA binding have been explored in recent studies[23,24]. Collectively, these studies showed that the decoding module of a translation-regulating T-box riboswitch exhibits a wide distribution of conformations, which undergo slow interconversion. tRNA binds directly to all conformers, each with unique kinetics. Binding promptly induces rapid rearrangement of the structural elements forming the decoding module, leading to a final, binding competent conformation. Furthermore, following tRNA dissociation, the decoding module returns to its original conformation prior to binding[24]. In addition, it has been shown that Mg^{2+} plays an important role in the global folding of the decoding module[23]. Here, using a larger construct that includes

the discriminator domain, the binding kinetics of tRNA$^{\text{Ile}}$ to both the decoding and discriminator domains of *Mtb ileS* T-box riboswitch are revealed, significantly expanding our understanding of the tRNA binding mechanism that leads to genetic switching. This work illuminates how the interplay of structural elements in T-box riboswitches leads to unique conformational dynamics in different T-box riboswitches with different roles in biological regulation.

By using smFRET characterization with the same fluorophore pair at equivalent positions in the T-box and tRNA ligand as in our previous studies on the *B. subtilis glyQS* T-box[19], the current study allows comparison of tRNA binding mechanisms between representative members of transcription- and translation-regulating T-box riboswitches. The data supports a similar two-step binding mechanism for the *Mtb ileS* T-box and *B. subtilis glyQS* T-box riboswitches, in which anticodon recognition by the decoding module occurs first, leading to the formation of a partially bound state, followed by binding of the tRNA NCCA end to the discriminator module to form the fully bound state (Fig. 8 and Supplementary Fig. 8). In both cases, the fully bound states are very stable, with a lifetime of at least 20 s, to secure sufficient time for transcriptional or translational outputs.

Besides the general resemblance regarding the two major binding states, the results reveal unique conformational heterogeneity and flexibility in the *Mtb ileS* T-box riboswitch. The first level of conformational flexibility is observed in the apo state of *Mtb ileS* T-box riboswitch, evocative of the complex conformational landscape of the decoding domain observed in previous smFRET studies[23,24]. In contrast

to the *B. subtilis glyQS* T-box, in which the intra-T-box conformational change involves an inward movement of the discriminator module relative to the decoding domain accompanied by the establishment of NCCA-discriminator interactions[19], the *Mtb ileS* T-box displays putatively open (zero FRET) and closed (0.3 state FRET) conformations in the absence of tRNA ligand (Figs. 5 and 8). Binding of either tRNA^Ile or tRNA^Ile-ΔNCCA can shift the equilibrium to the closed state from the open state, with tRNA^Ile being more effective than tRNA^Ile-ΔNCCA. However, no reversible transitions between the zero and 0.3 FRET states were observed, suggesting that the transition rate between the open and closed conformations may be slower than the imaging time window (~30 s). Therefore, it is not possible to determine the transition rates between the two conformations or conclude whether tRNA binds preferentially to one state over the other. Future 3-color smFRET experiments are needed to fully explore this mechanistic detail. Nevertheless, since binding of tRNA shifts the equilibrium to the closed conformation, it is most likely that the closed conformation corresponds to the conformation after tRNA binds.

The second level of conformational flexibility is observed in the partially bound state of the *Mtb ileS* T-box riboswitch, where only the anticodon-specifier but not the NCAA-discriminator interactions have been established. The partially bound state in the *B. subtilis glyQS* T-box exhibits a homogenous population, with a lifetime of ~3.6 s before the tRNA dissociates[19]. In contrast, the partially bound state of *Mtb ileS* T-box, represented by the experiments using tRNA^Ile-ΔNCCA, exhibits two populations (Figs. 4 and 8). Around 73% of the population only samples the 0.5 FRET state (One-state population) with a lifetime of ~6.3 s before the tRNA dissociates. The lifetime of the bound tRNA is noticeably longer in the remaining 27% of the population. In this population, the bound tRNA rapidly transitions between 0.5 and 0.7 FRET states (Two-state population), with the latter resembling the fully bound state when using an uncharged intact tRNA. However, without the possibility to establish the NCCA-discriminator interactions, the lifetime of the 0.7 FRET state in the Two-state population is two orders of magnitude shorter than the 0.7 FRET state representing the fully bound state with an uncharged intact tRNA. Considering both the One-state and Two-state populations, the average lifetime of the partially bound state (17.3 s) in the *Mtb ileS* T-box complex is 5-fold longer than that for the *B. subtilis glyQS* T-box. While the exact molecular architectures associated with the conformational heterogeneity observed in the Two-state population remains unclear, this observation suggests that the *Mtb ileS T-box* riboswitch can sample dynamically the fully bound conformation to attempt interactions between the tRNA NCCA end and the discriminator module, and that the presence of the uncharged tRNA NCCA end greatly stabilizes the fully bound conformation. While it is not possible to directly infer the interconversion between the two populations, it is reasonable to assume that the One-state population is able to transit into the Two-state population. This is due to the fact that the Two-state population represents only 27% of the partially bound state, whereas ultimately 71% of the population is able to reach the fully bound state in the presence of an intact uncharged tRNA. Taken together, these findings support the notion that while binding of the tRNA NCCA to the *B. subtilis glyQS* T-box may employ an induced-fit model, binding of tRNA NCCA to the *Mtb ileS* T-box is likely to use a conformational selection model.

Although the *B. subtilis glyQS* and *Mtb ileS* T-boxes constructs kinetically examined so far lack, respectively, the terminator and sequestrator sequences, the differences in the kinetic features of these two types of T-box riboswitches may be functionally linked to the temporal constraints of their regulation. In the case of *B. subtilis glyQS* T-box, the lower minimum free energy (MFE) of the terminator compared to the antiterminator structure (Supplementary Fig. 9b) indicates that terminator is likely to be the preferred conformation in the absence of a tRNA ligand. In order to lock the antiterminator configuration, an uncharged tRNA needs to fully bind cotranscriptionally before transcription and folding of the antiterminator region, otherwise the terminator will form. The time needed for this decision is short. Therefore, a short lifetime of the partially bound state can avoid trapping the *glyQS* T-box-tRNA in the terminator state and potentially allow multiple sampling events of tRNA ligands. *Mtb ileS* T-box regulates at the translational level, but the actual timing of this type of regulation is unclear. Interestingly, the difference in MFE between sequestrator and antisequestrator is smaller (Supplementary Fig. 9) compared to that of the *B. subtilis glyQS* T-box terminator and antiterminator. In addition, the *Mtb ileS* T-box antisequestrator has lower MFE than the *B. subtilis glyQS* T-box antiterminator (Supplementary Fig. 9a, b). This suggests that in the absence of a tRNA ligand: 1) The bias of *Mtb ileS* T-box towards folding into the sequestrator over the antisequestrator conformation cotranscriptionally is less pronounced compared to the terminator over antiterminator conformation in the *glyQS* T-box; 2) the antisequestrator conformation, if formed during transcription, is more stable throughout transcription; and 3) conformational rearrangements between antisequestrator and sequestrator states may occur post-transcriptionally in the absence of tRNA ligand. Given these possibilities, translational regulation by the *Mtb ileS* T-box may not be limited to be cotranscriptional but could also occur post-transcriptionally. Indeed, regulation by *trans*-acting small RNAs has also been observed to occur both co- and post-transcriptionally, with their actual contributions depending on the timing of transcription, transcript folding, and small RNA binding[29,30]. In this context, a short lifetime of the partially bound state would not provide any functional benefits for *Mtb ileS* T-box riboswitch. In contrast, a longer lifetime of the partially bound state may allow sufficient time for the establishment of the NCCA-discriminator interactions, through conformational sampling, and downstream conformational changes in the sequestrator/antisequestrator region.

Finally, our results highlight two critical sequence elements that facilitate tRNA binding and NCCA end discrimination. First, previous studies emphasized the central role of the Stem IIA/B-linker pseudoknot as a topological hinge that controls the conformations of Stems I and II[14]. Consistent with this previous finding, the data from the Linker Mutant further illustrates that the A-minor interaction and the pseudoknot structure are critical for the stability of both the partially bound state and the fully bound state. The critical importance of these interactions helps explain the conservation of the 'F-box' sequence in T-boxes (nucleotides 77-81, CGUCA in Mtb ileS T-box)[31]. Second, the present data elucidate the kinetic impact of the conserved RAG sequence on NCCA discrimination. Structural studies demonstrate that the RAG motif establishes specific interactions with the uncharged tRNA NCCA end. The results here demonstrate that mutating the RAG motif leads to the formation of a pseudo fully bound state, in which the tRNA NCCA end interacts with the discriminator domain with a distinct, likely non-functional configuration. This observation indicates that the RAG motif provides specificity for NCCA binding by constraining the conformational flexibility and reducing sampling of an aberrant NCCA docking state. While no equivalent measurement is available for a transcription-regulating T-box, given the structural similarity of the core discriminator domain and tRNA, it is possible to speculate that the conserved RAG motif may function in the same way in transcription regulating T-boxes as it does in *Mtb ileS* T-box.

In summary, the current work together with previous kinetic characterization on the decoding domain[23,24] provides a more complete picture of tRNA ligand binding process by a representative translational T-box riboswitch (Fig. 8). The differences in the kinetic features of *glyQS* and *ileS* T-box riboswitches may reflect a fundamental functional difference between the two types of T-box riboswitches. In addition, the A81:G68:C77 A-minor interaction and the pseudoknot structure formed by Stem IIA/B and the linker region critically coordinate with both binding steps and enhance the stability of the partially bound and fully bound states. Finally, the conserved

RAG sequence constrains the binding pocket of the tRNA NCCA end and provides specificity to NCCA recognition by limiting conformational flexibility. Overall, these findings shed light on the sophisticated and dynamic nature of T-box-tRNA interactions, highlighting the complex interplay between structural motifs, conformational flexibility, and ligand binding kinetics. By characterizing the nuanced structural adaptations that enable novel conformational dynamics, these results provide a more comprehensive framework to understand how structured RNA-based regulatory systems adapt to new regulatory niches.

Methods

Template DNA preparation

DNA templates, encompassing the sequence of interest placed downstream of a T7 promoter followed by a BsmI restriction site, were synthesized, and cloned into a pUC19 vector by GenScript (Jiangsu, China). For each plasmid, after transformation into *E. coli* DH5α cells, a minimum of 1 L of culture was grown overnight at 37 °C shaking at 200 rpm in Lysogeny Broth (LB) supplemented with ampicillin (at a final concentration of 100 μg/ml). Cells were harvested by centrifugation at 5470 x g for 30 min at 4 °C. Each cell pellet from a 1 L culture was resuspended in 10 ml of GTE buffer (50 mM glucose, 25 mM Tris-HCl pH 8.0, 10 mM EDTA, and 0.1 mg/ml RNase A), followed by addition of 20 ml of 0.2 M NaOH and 1% SDS to lyse the cells and left to stand on ice for five minutes. After neutralizing the lysate with 15 ml of 3 M potassium acetate (pH 5.2), the mixture was left on ice for ten min. In order to precipitate the DNA, the lysate supernatant was mixed with 0.6 volume of isopropanol followed by incubation at −20 °C for 15 min. The solution was centrifuged for 30 min at 4 °C at 4000 x g and the supernatant was discarded. The DNA pellet was washed repeatedly with 80% ethanol and then resuspended in 2 ml of TE buffer (10 mM Tris pH 8.0, 0.1 mM EDTA). To eliminate RNA contamination, RNase A (4 mg/ml, final concentration 20 μg/ml) was added and incubated at 37 °C for 20 min. Equal volumes of phenol/chloroform (1:1) were used twice to extract the DNA, followed by addition of 10% (v/v) 3 M sodium acetate pH 5.5 to precipitate the mixture. The precipitated DNA was rinsed twice with 80% ethanol before precipitation by centrifugation at 4000 x g for 30 min at 4 °C. After resuspension in 4 ml of TE buffer, 1.2 ml of 40% PEG 8000 and 516 μl of 5 M NaCl were added, and the mixture was left to precipitate overnight at 4 °C. The precipitated plasmid DNA was recovered by centrifugation at 4000 x g for 30 min at 4 °C, re-suspended in water, and ethanol precipitated again using 3 M sodium acetate pH 5.5 overnight at −20 °C. After three 80% ethanol washes, the pellet was once again resuspended in 1 ml of water. The concentration and purity of the purified plasmid DNA was assessed by measuring the absorbance ratio (A_{260}/A_{280}) using a Nanodrop spectrophotometer (Thermo Scientific) and aiming for a 1.9 ratio. Plasmids DNA were kept at 4 °C until needed. To confirm and validate the plasmid, the entire plasmid was sequenced (Primordium Laboratories).

Fluorophore conjugation of DNA oligonucleotides

For intermolecular smFRET experiments, DNA oligonucleotides containing an amine modification at the 3′ end and a biotin modification at the 5′ end were synthesized by Integrated DNA Technologies (IDT, Coralville IA). For intramolecular smFRET experiments, an additional DNA oligonucleotide containing an amine modification at the 5′ end was synthesized by IDT. To attach either Cy5 or Cy3 to these oligos, 13.5 μl of the 100 μM DNA oligonucleotide was thoroughly mixed with 1.5 μl of 1 M NaHCO3 pH 8.6. Following this, a pre-prepared solution containing 25 μg of N-hydroxysuccinimide (NHS)-conjugated fluorophore (either Cy3 or Cy5 (Lumiprobe, Hunt Valley, MD)) dissolved in 0.5 μl DMSO was added to the DNA oligonucleotide mixture. The mixture was incubated at a constant 37 °C temperature overnight to ensure proper conjugation. To precipitate the conjugated DNA

oligonucleotide, 1.67 μl of 3 M sodium acetate pH 5.5 and 50 μl of pure ethanol were added to the mixture, followed by overnight incubation at −20 °C. Post incubation, the mixture was centrifuged at 21000 x g for 30 min. The resulting pellet, containing the conjugated DNA oligonucleotide, was then resuspended in 40 μl of water. To ensure the removal of any residual free dye and salt, the DNA solution was passed through a Micro Bio-Spin 6 column (Bio-Rad, Hercules, CA). The concentrations of oligo and conjugated fluorophore were measured using a Nanodrop spectrophotometer. The labeling efficiency for all labeled oligonucleotides was estimated to be at least 90%.

T-box preparation

The RNA molecules were synthesized by in vitro transcription from a linearized DNA template. To linearize the template, plasmids purified as described above harboring the region of interest were digested with BsmI (NEB, Ipswich MA). The reaction mixture was prepared in a nuclease-free microcentrifuge tube, consisting of 100 μg of plasmid DNA, 500 units of BsmI, the appropriate volume of 10X rCutSmart™ Buffer, and nuclease-free water to bring the final concentration of enzyme to less than 5% (v/v). The tube was then incubated in a constant temperature water bath at 65 °C, for 1 h. Post incubation, the reaction was assessed for completion through gel electrophoresis. The digested product was then purified by two phenol-chloroform extractions, ethanol precipitated, and resuspended in nuclease-free water, and the concentration of the digested product was measured using a Nanodrop spectrophotometer.

For T-box sample preparation the samples were purified from the transcription reaction without any denaturing steps. Transcription reactions were set up in a total volume of 500 μl, containing 50 μg of linearized DNA template, 40 mM Tris-HCl pH 8.0, 10 mM MgCl₂, 1 mM spermidine, 50 μg/ml BSA, 20 mM DTT, 5 mM of ATP, CTP, and UTP, 6 mM of GTP, 80 U of Recombinant RNase inhibitor (Promega, Fitchburg, WI), 8 U of inorganic pyrophosphatase (Sigma-Aldrich, St. Louis, MO), and 5 U of T7 RNA polymerase (purified in-house). A Cy3-labelled DNA oligonucleotide was added to a final concentration of 1 μM to the transcription reaction to promote cotranscriptional annealing to the 3′- extension of the T-box sequence. The mixture was gently mixed by pipetting and incubated at 37 °C overnight. The next day, transcription reactions were briefly centrifuged to separate precipitated material before being loaded to a Superdex 200 10/200 GL column (Cytiva) pre-equilibrated with SEC buffer (10 mM Tris pH 7.4, 100 mM KCl, and 20 mM MgCl₂). The column was run with an isocratic flow at 0.5 ml/min, and fractions were collected between 11.5 and 14 ml, depending on the mutant (Supplementary Fig. 1). Collected fractions were concentrated to ~40 μl by ultrafiltration using a Vivaspin 500 (Vivaproducts, Littleton, MA) centrifugal concentrator with a 3 kDa MWCO. The concentration of Cy3 in the concentrated fractions was measured using a Nanodrop spectrophotometer. One volume of 50% glycerol was subsequently added to the concentrated fractions before aliquoting, flash-freezing in liquid nitrogen, and storing at −80 °C.

tRNA preparation

For tRNA sample preparation, transcription reactions were set up in a total volume of 5 ml, containing 500 μg of linearized DNA template, 40 mM Tris-HCl pH 8.0, 10 mM MgCl₂, 1 mM spermidine, 50 μg/mL BSA, 20 mM DTT, 5 mM of ATP, CTP, and UTP, 6 mM of GTP, 800 U of Recombinant RNase inhibitor (Promega, Fitchburg, WI), 8 U of inorganic pyrophosphatase (Sigma-Aldrich, St. Louis, MO), and 5 U of T7 RNA polymerase (purified in-house). The mixture was gently mixed by pipetting and incubated at 37 °C overnight. One volume of 50% glycerol was subsequently added to the transcription reaction before aliquoting, flash-freezing in liquid nitrogen, and storing at −80 °C. Transcription samples were purified by urea-polyacrylamide gel electrophoresis (urea-PAGE) by cutting out the tRNA band. The excised gel slice was electroeluted using an EluTrap device (Whatman). After

electroelution, tRNA was precipitated by the addition of 3 volumes of 100% ethanol and 1/10th volume of 3 M sodium acetate (pH 5.5), followed by incubation at −20 °C for at least 1 hour. The tRNA was then pelleted by centrifugation at 12000 x g for 15 min at 4 °C, and the supernatant was discarded. The tRNA pellet was washed twice with 70% ethanol, centrifuged again at 12000 x g for 5 min at 4 °C. The tRNA pellet was dried using a SpeedVac vacuum concentrator (Savant) for 2–5 min and resuspended in an appropriate volume of nuclease-free water. The concentration of the purified RNA was assessed using a Nanodrop spectrophotometer. The purified tRNA was aliquoted and flash-frozen using liquid nitrogen and stored at −80 °C until further use.

For 5′ end labelling of tRNA, the N-(3-Dimethylaminopropyl)-N′-ethylcarbodiimide hydrochloride (EDC) – NHS coupling method[32] was followed, wherein the 5′ monophosphate of the RNA is activated by EDC and imidazole for subsequent labelling. First the 5′ triphosphate of RNA was converted into a 5′ monophosphate by incubating 100 µg RNA with 100 units of RNA 5′ Pyrophosphohydrolase (NEB, Ipswich MA) at 37 °C for 1 hour within a 100 µl reaction volume. Following this, the enzyme was removed by phenol chloroform extraction followed by passing the supernatant through a Micro Bio-Spin 6 column to exchange to a 10 mM HEPES pH 7.0, 150 mM NaCl, and 10 mM EDTA buffer. After the buffer exchange, the RNA solution was treated with 12.5 mg of EDC, 50 µl of ethylene diamine, and 200 µl of a 0.1 M imidazole pH 6.0 buffer. This mixture was then incubated for 3 hours at constant 37 °C temperature. Post incubation, the RNA was ethanol precipitated and the pellet was resuspended in 0.1 M sodium carbonate pH 8.7 buffer. Any residual EDC was removed by passing the solution through a Bio-Spin 6 column. For the final labelling step, the RNA solution in 0.1 M sodium carbonate pH 8.7 buffer was incubated with Cy5 NHS (Lumiprobe, Hunt Valley, MD) dye for 45 min, using an approximate RNA to dye molar ratio of 1:200 followed by ethanol precipitation and RNA resuspension in water. To remove any residual free dye, the final RNA solution was passed through a Micro Bio-Spin 6 column. The labeling efficiency of tRNAs was consistently around 90%-100%.

Refolding tRNA for smFRET or BLI experiments was done by initially diluting it to the required final concentration in a solution containing 10 mM HEPES pH 7.5 and 50 mM NaCl. The sample was then heated to 95 °C using a thermocycler, incubated for 3 min, and then transferred to ice to cool it rapidly for 3 min. After cooling, MgCl₂ was added to a final 15 mM concentration. The tRNA solution was heated to 50 °C in a thermocycler and incubated for 10 min at this temperature, followed by a 30 min incubation at 37 °C. Lastly, the sample was removed from the thermocycler and allowed to equilibrate to room temperature. For BLI binding assays, the folded tRNAs were dialyzed into 10 mM Tris pH 7.4, 100 mM KCl, and 20 mM MgCl₂. For smFRET studies, one volume of 50% glycerol was added to the tRNA solution, aliquoted and flash frozen in liquid nitrogen for long-term storage prior to use.

Biolayer interferometry assays

Biolayer Interferometry (BLI) was used to determine the equilibrium dissociation constant (K_D) of *Mtb-ileS* T-box and tRNA^{Ile} using streptavidin biosensors (SAX) in an Octet K2 system (FortéBio Inc. San Jose, CA). The assays were performed on black, flat-bottom 96-well microplates (Greiner Bio-One 655209) in a total volume of 200 µl with orbital shaking at 1000 rpm. The instrument was controlled with the Data Acquisition 11.1 (FortéBio Inc. San Jose, CA) software package. Before each experiment, biosensors were hydrated in SEC buffer (10 mM Tris pH 7.4, 100 mM KCl and 20 mM MgCl₂). At the start of each experiment, a baseline was established using SEC buffer for 30 seconds. Subsequently the T-box at a 7.5 ng/µL concentration in SEC buffer was bound to the streptavidin sensor for 250 seconds, followed by washing for 30 seconds with the same buffer to eliminate non-specific binding

and establish a pre-association baseline. Next, the purified and refolded tRNA was introduced into the biosensor and the association signal was measured for up to 500 seconds, until apparent equilibrium was reached at the highest concentration. Finally, the dissociation curves were obtained by moving the biosensors back into wells with SEC buffer (Supplementary Fig.1b). Each BLI experiment was done at several different tRNA concentrations (measured before each experiment) in the 1.6 to 55.3 µM range. For each set of experiments, a sensor that was not loaded with any T-box was used as a negative control and reference well for later data subtraction. New streptavidin biosensors were used for each experiment.

The raw data were preprocessed using the Octet Data Analysis Software version 11.1 (FortéBio Inc. San Jose, CA). Preprocessing included Y-axis alignment, reference subtraction, and interstep correction to account for noise while sensors are moved between solutions. Three binding models were considered to describe the binding kinetics: a one-step binding model, a parallel one-step binding model, and a sequential two-step binding model. Data were fit to the three considered models using either the Octet Data Analysis Software version 11.1 (FortéBio Inc. San Jose, CA) for the one-step and parallel one-step binding models, or a custom software for the two-step binding model. To prepare the data for our custom model fitting software, preprocessed data files were exported from the Octet Data Analysis software and converted to plain text (.txt). These data were then processed using Python scripts in Jupyter notebooks to fit the data to the sequential two-step binding model. Due to the high multicollinearity of the model fitted to the data, the standard method to estimate parameter errors by extracting the diagonal elements of the covariance matrix of the regression model led to artificially inflated variances and, in turn, standard errors. Thus, the estimation of parameter errors was performed using a residuals bootstrapping approach. For this purpose, initial fitting was done using the curve_fit function from the scipy.optimize module in Python, which provided the best-fit values for nonlinear fitting of all parameters for each dataset. The residuals between the original data and the fitted values were then calculated. Bootstrapping was performed for 10000 cycles. In each cycle, a new set of bootstrap data were generated by randomly sampling the residuals with replacement and adding them to the original values. Nonlinear fitting was then repeated on these bootstrap data using the same initial guesses and parameter bounds as the original fit. The resulting best-fit parameters and R-squared values from each bootstrap cycle were stored. The means and standard deviations of the bootstrap parameter distributions were then calculated to estimate the parameter uncertainties. Jupyter notebooks containing the code used to fit and plot these data are provided in the Source Data. A detailed description of the mathematical model used to fit these data is provided in the Supplementary Information and the Jupyter Notebooks.

smFRET measurement

Quartz slides and glass coverslips for total internal reflection fluorescence microscopy were prepared according to previously published protocols[33,34]. The surface of the slides and coverslips were coated with a mixture of poly-ethylene glycol (PEG, Mw = 500,000) and biotin-PEG (Mw = 500,000). Microfluidic channels were constructed between the slides and coverslips as previously described in refs. 33,34. The channels were further passivated with a solution of 10 µM BSA to prevent non-specific binding, followed by incubation with a solution containing 10 µM BSA and 1 µM streptavidin. An aliquot of folded T-box riboswitch, carrying the labeled and biotinylated DNA oligo, was diluted to a concentration of 0.5-1 nM, and immobilized to the surface of the chamber via biotin-streptavidin interactions. tRNA was diluted to a concentration of 100 nM in an imaging buffer comprising of 50 mM HEPES pH 7.0, 100 mM KCl, 15 mM MgCl₂, 5 mM protocatechuic acid (PCA) (Sigma), 1 U/mL protocatechuate-3,4-

dioxygenase (PCD) (MP Biomedical), and 2 mM Trolox (Sigma), and was flowed into the microfluidic channel. For the intramolecular smFRET experiments, the concentration of the dual labeled T-box RNA was 1 nM and the unlabeled tRNA concentration was either 5 or 13 μM. An objective based total internal reflection fluorescence (TIRF) microscope based on a Nikon Ti-E with 100X NA 1.49 CFI HP TIRF objective (Nikon) was used to perform the smFRET measurements. A 561 nm laser (Coherent Obis at a power density of 4.07×10^5 W/cm^2) and a 647 nm laser (Cobolt MLD at a power density of 5.88×10^5 W/cm^2) were used for Cy3 and Cy5 excitation respectively. Emissions from both donor and acceptor were passed through an emission splitter (OptoSplit III, Cairn), and collected at different locations on an EMCCD (iXon Ultra 888, Andor). For intermolecular FRET measurement, 1500 frames of time-lapse images were taken with 100 ms exposure time and 561 nm laser excitation. For the intramolecular FRET measurements, 5 frames of time-lapse images with 100 ms exposure time and 647 nm laser excitation were taken before the FRET recording using the 561 nm laser excitation. The biological samples (i.e. the in vitro transcribed tRNAs and T-boxes) were generated at least twice, each considered as a biological replicate. For each biological replicate, at least three technical replicates were done. In each measurement, T-box and tRNA were diluted, smFRET images were recorded, and analysis were performed independently. Before each smFRET experiment, Tetraspeck beads (ThermoFisher) were used to align the emission channels. NIS Elements software was used for all smFRET data acquisition.

Transition rates and lifetime analyses

NIS Elements software was used to pick individual spots and generate intensity trajectories from the time-lapse images. For intermolecular FRET experiments, maximum intensity projection of Cy5 emission signal was generated, and signals above an intensity threshold were selected to generate regions of interest (ROIs). For the intramolecular FRET measurements, maximum intensity projection of Cy5 emission signal from the 5 frames with Cy5 direct excitation was generated, and signals above an intensity threshold were selected to generate ROIs. ROIs were projected into the Cy3 and Cy5 channels in the time-lapse images to generate Cy3 and Cy5 intensity trajectories. Fluorescence intensity trajectories were corrected for baseline and bleed-through in MATLAB as previously described in ref. 33. FRET traces were generated by calculating $I_{Cy5} / (I_{Cy5} + I_{Cy3})$ at each time point from the intensity trajectories.

Idealization of FRET trajectories was achieved using the global modeling algorithm in tMAVEN[26] unless otherwise specified. The following settings for the parameters of the priors were used: α: 1.0, β: 0.25, π: 1.0, a: 2.5, b: 0.01. The prior b was set to 0.4 for the Linker Mutant and 0.2 for the RAG Mutant. When a global modeling approach was used, transition rates were directly extracted from the transition matrix output of tMAVEN (Supplementary Table 5). Mean lifetime values calculated from these transition rates are also described in Supplementary Table 5. To calculate errors in transition rate matrices (Supplementary Table 5), variances of the un-normalized counts matrix output by tMAVEN were calculated using the following Dirichlet variance formula:

$$var[x_i] = \frac{\widetilde{\alpha}_i(1 - \widetilde{\alpha}_i)}{\alpha_0 + 1} \qquad (1)$$

where $\widetilde{\alpha}_i = \frac{\alpha_i}{\alpha_0}$, α_i is the i entry of the counts matrix, and α_0 is the sum of the row x_i is in. Upper and lower bounds on the rates were calculated using the following relation between transition probabilities and rate constants:

$$k = -\frac{ln(1 - p)}{\Delta t} \qquad (2)$$

where Δt is the frame rate of data acquisition. To get upper and lower bounds for lifetimes calculated by either transition rate analysis or dwell time analysis, the error propagation formula was used:

$$\Delta F(x_1, x_2, \ldots) = \sqrt[2]{\sum_i \left(\frac{\partial F}{\partial x_i}\right)^2 \Delta x_i^2} \qquad (3)$$

where a function F depends on variables $x_1, x_2, \ldots$, each with their respective errors $\Delta x_1, \Delta x_2, \ldots$. Jupyter notebook files with error propagation calculations are provided in the Source Data files.

Since global modeling is equivalent to concatenating the ensemble of trajectories into a single, long trajectory, which is then analyzed with an HMM, this approach may be insensitive to infrequently and transiently sampled states. Therefore, in the analysis of two sub-populations in the partially bound state using WT *Mtb ileS* T-box and tRNAIle$^{-\Delta NCCA}$-Cy5, a composite approach was used. Traces of the One-state population were analyzed by a variational Bayesian algorithm clustered by K-means (composite HMM + K-means)[26]. This approach infers an HMM for each trace and then clusters the inferred FRET means for each HMM using K-means, allowing it to capture more accurately the 0.5 FRET events of each trace. Modeling of the Two-state population was achieved using the variational Bayesian Gaussian mixture modelling (vbGMM) algorithm in tMAVEN[26]. This approach assumes that all the data points are generated from a mixture of a finite number of Gaussian distributions with unknown parameters and best identified the short-lived 0.7 FRET state.

In all cases, lifetimes were also calculated using either single or double exponential fitting to the dwell time histogram for each FRET state before transitioning out of that state using tMAVEN[26]. In most of the cases, the single-exponential decay fitting is sufficient to describe the dwell time data (when A > 0.75). For the cases where A < 0.75, the double-exponential decay fitting was selected (Supplementary Table 6).

IntraFRET data analysis

The FRET state population analysis for the IntraFRET sample was analyzed using custom software provided in the Source Data as a Jupyter notebook. Fluorescence intensity trajectories were read from files, each containing paired columns of donor and acceptor fluorescence intensities. To ensure consistent sampling before photobleaching, we considered the first 400 data points from each file. The FRET efficiency for each pair of donor (I_D) and acceptor (I_A) intensities was calculated using the formula:

$$E_{FRET} = \frac{I_A}{I_D + I_A} \qquad (4)$$

Efficiencies were computed for all paired columns in the data set, and the results saved for subsequent analysis. The histogram data were then fit to a double Gaussian model defined as:

$$G(x) = A_1 \exp\left(-\frac{(x - \mu_1)^2}{2\sigma_1^2}\right) + A_2 \exp\left(-\frac{(x - \mu_2)^2}{2\sigma_2^2}\right) \qquad (5)$$

where (A_1) and (A_2) are the amplitudes, (μ_1) and (μ_2) are the means, and (σ_1) and (σ_2) are the standard deviations of the two Gaussian components. The parameters were estimated using non-linear least squares fitting. The area under each Gaussian curve was computed to determine the contributions of each FRET population. The area (A_i) under each Gaussian component is given by:

$$A_i = A_i' \sqrt{2\pi}\sigma_i \qquad (6)$$

where (A_i') is the fitted amplitude, and (σ_i) is the fitted standard deviation. The errors of these areas were propagated from the fitting

uncertainties using the following formula:

$$\Delta A_i = \sqrt{\left(A_i'\sqrt{2\pi}\Delta\sigma_i\right)^2 + \left(\sigma_i\sqrt{2\pi}\Delta A_i'\right)^2} \tag{7}$$

where $(\Delta\sigma_i)$ and $(\Delta A_i')$ are the standard errors of the fitted parameters. The total area under both Gaussians was calculated as the sum of the individual areas, and its error as the root sum square of the individual errors. The ratio of the areas under the two Gaussian components was computed to quantify the relative contributions of the two populations. The error in this ratio was propagated using standard error propagation formulas:

$$R = \frac{A_2}{A_1 + A_2} \tag{8}$$

$$\Delta R = R\sqrt{\left(\frac{\Delta A_2}{A_2}\right)^2 + \left(\frac{\Delta(A_1+A_2)}{A_1+A_2}\right)^2} \tag{9}$$

Diagrams of the *Mtb ileS* T-box were made using PyMOL[35] based on the coordinates of the structure of the complex[14] (PDB ID 6ufg, 6ufh).

Reporting summary

Further information on research design is available in the Nature Portfolio Reporting Summary linked to this article.

Data availability

The raw data supporting the findings of this study are available from the corresponding authors upon request. Source data for the figures and Supplementary Figs. are provided as a Source Data file. Source data are provided with this paper.
